Abstract

We develop a model-based approach to measure CEO value in privately held businesses, holding fixed inputs chosen by owners while substituting out variable inputs optimized by managers. Using the universe of Hungarian firms and their CEO networks over three decades (1992-2022), we estimate skill differences that translate into measurable productivity impacts. Most importantly, we develop a novel placebo-controlled event study design that reveals 75 percent of typical fixed-effect estimates reflect noise rather than true CEO effects. The naive comparison shows firms hiring better CEOs outperform those hiring worse CEOs by 22.5 percent, but placebo transitions—randomly assigned fake CEO changes excluding actual transition periods—generate a 17.0 percent spurious effect. The true causal impact is thus 5.5 percent: statistically significant and economically meaningful, but only 25 percent of the raw correlation. This methodology addresses a fundamental identification challenge in the managerial effects literature and suggests new approaches for using CEO quality measures in empirical work.

*Project no. 144193 has been implemented with the support provided by the Ministry of Culture and Innovation of Hungary from the National Research, Development and Innovation Fund, financed under the KKP_22 funding scheme. This project was funded by the European Research Council (ERC Advanced Grant agreement number 101097789). 1 Introduction

How much do CEOs matter for firm performance? The answer has profound implications for corporate governance, executive compensation, and economic policy, yet measuring CEO value remains one of the most challenging problems in empirical economics. While a large literature documents substantial manager effects—Bertrand & Schoar (2003) document sizable heterogeneity in managerial “styles” affecting policies (investment, leverage, etc.) rather than a single causal ROA estimate, and Metcalfe et al. (2023) find sizable, context-dependent manager contributions to store performance with magnitudes sensitive to mobility/composition and identification—these estimates may substantially overstate true CEO importance.

The fundamental challenge is separating genuine managerial skill from spurious correlations. The econometric literature has long recognized this problem: Gaure (2014) develops a correction framework that highlights potential correlation bias in two-way fixed effects models; Bonhomme et al. (2023a) emphasize that limited mobility can induce bias whose severity depends on mobility patterns; and Andrews et al. (2008) study assortative matching in wages, with implications that estimates can be attenuated, but magnitudes are context-specific. These concerns suggest standard approaches may overstate individual managers’ importance in some settings.

This measurement problem is particularly acute for privately held businesses, which constitute the vast majority of economic activity worldwide yet remain understudied due to data limitations. While public companies provide stock returns and detailed compensation data, private firms offer neither, requiring new approaches to value measurement. The limited evidence on private firms reveals important differences: Cole & Mehran (2008) and Gao & Li (2015) document compensation differences between public and private firms (levels and pay–performance sensitivity). These patterns speak to contracting environments rather than directly to discretion or control rights. Intriguingly, Quigley et al. (2022) report differences in CEO contributions to performance across ownership forms; estimated magnitudes vary across samples and methods, so we avoid a single headline gap. Moreover, existing studies typically examine hundreds or thousands of firms, limiting statistical power to separate signal from noise in manager effects.

Against this backdrop, quasi-experimental evidence provides sobering benchmarks. Bennedson et al. (2020) exploit CEO hospitalizations as exogenous shocks in Danish firms, finding that permanent CEO absence would reduce returns by roughly 7 percent—substantial, but far smaller than correlational estimates suggest. Similarly, Chandra et al. (2016) find hospital manager effects explain only 5 percent of risk-adjusted mortality variance after accounting for patient selection. Structural estimation provides converging evidence: Page (2018) find that while CEO attributes explain most compensation variation, removing CEO influence would increase shareholder value by only 1.7 percent, with the largest gains (29 percent) coming from removing all agency frictions rather than CEO effects per se. These causal estimates hint that true CEO effects, while meaningful, are much smaller than standard methods imply.

This paper addresses these challenges by developing a novel methodology to measure CEO value in privately held businesses and applying it to the universe of Hungarian firms over three decades. Our approach reveals a startling finding: approximately 75 percent of what standard methods identify as CEO effects are spurious. The true causal impact of CEO quality on firm performance is 5.5 percent—economically meaningful but only one-quarter of the raw correlation.

We make four main contributions:

First, we develop a placebo-controlled event study methodology that separates true CEO effects from spurious correlations. By constructing placebo CEO transitions—randomly assigned fake changes that exclude actual transition periods—we isolate mechanical biases from genuine impacts. The naive comparison shows firms hiring better CEOs outperform those hiring worse CEOs by 22.5 percent. Remarkably, placebo transitions generate a 17.0 percent effect despite no actual management change. The true causal impact is thus 5.5 percent: the difference between actual and placebo effects.

Second, we ground this empirical strategy in a model-based framework that clarifies what we can and cannot measure. Building on Lucas (1978) and decreasing returns models of Atkeson & Kehoe (2005); McGrattan (2012), we explicitly separate owner-controlled inputs (capital, organizational structure) from manager-controlled inputs (labor, materials). This distinction is crucial: CEOs receive credit for many factors outside their control. Our framework identifies the marginal contribution of CEO skills to firm surplus while holding fixed the inputs chosen by owners.

This separation between owner and manager decisions reflects the institutional reality of private firms. Theoretical frameworks establish that concentrated ownership inherently limits managerial discretion (Fama & Jensen, 1983; Jensen & Meckling, 1976). Burkart et al. (2003) model how founding families retain control rights even when hiring professional CEOs, preserving their ability to override investment decisions.

Empirical evidence confirms these predictions. Management and Organizational Practices Survey (MOPS) evidence indicates many U.S. manufacturing plants have limited capital authorization (Bloom et al., 2019; Buffington et al., 2017). A commonly cited \$10,000 cutoff appears in presentations (e.g., Bloom et al. 2019) rather than a published consensus figure, so we treat it as illustrative rather than universal. When plant managers throughout the U.S. manufacturing sector face such stringent investment limits, it underscores how pervasive centralized control over capital allocation is—and suggests that CEOs in private firms, particularly family-controlled businesses, operate under similarly tight constraints from their owners.

Further international evidence comes from Bloom et al. (2012), who document that family-owned firms exhibit more centralized decision-making than dispersed-ownership firms across 20 countries. Our analysis of their data (Table A0) suggests family ownership is associated with lower investment autonomy for plant managers in private firms (our calculation: approximately 37%). While this measures plant manager rather than CEO autonomy, the pattern is clear: ownership concentration is associated with more centralized decision rights over capital allocation. We emphasize that the 37% figure is our secondary calculation using their data and is not reported in Bloom et al. (2012).

Third, we implement this approach using extraordinary data: the universe of Hungarian firms over three decades (1992-2022). We track 1,063,172 firms and 1,030,470 unique CEOs, identifying a connected network of 189,108 managers who lead multiple firms. This scale dwarfs previous studies—Fee et al. (2013) examine 500 firms, Fenizia (2022) study 433 public administrations, even Metcalfe et al. (2023) cover 66,000 stores. Our data enables precise estimation of manager effects through 51,736 firms with exactly one CEO change, providing statistical power

to separate signal from noise that smaller samples cannot achieve.

Fourth, we provide practical guidance for future research using manager quality measures. Given that 75 percent of apparent CEO effects reflect noise, researchers should: (i) incorporate observable manager characteristics to reduce measurement error; (ii) place CEO quality measures on the left-hand side of regressions where noise is less problematic; (iii) never use them as right-hand side variables where attenuation bias dominates; (iv) avoid simple correlations where inflated variance misleads. These guidelines have immediate implications for the large literature using manager fixed effects.

Our findings reconcile the seemingly contradictory evidence on CEO importance. The true causal effect of 5.5 percent aligns remarkably with quasi-experimental studies, confirming that CEOs matter but far less than correlational estimates suggest. This has profound implications: policies targeting managerial quality will have more modest impacts than raw correlations imply, executive compensation debates rest on inflated effect sizes, and much of the variation in firm performance attributed to leadership reflects other factors. By providing a methodology to separate signal from noise in manager effects, we enable more rigorous analysis of when, how, and how much management matters for economic outcomes.

2 Modeling Framework

Firms produce output using a Cobb-Douglas production function that incorporates both fixed and variable inputs. Owing to the presence of fixed inputs, technology exhibits decreasing returns to scale. This will pin down the scale of the firm even when markets are perfectly competitive and the firm is a price taker in both input and output markets (Atkeson & Kehoe, 2005; McGrattan, 2012).¹

The production function for firm i with manager m at time t is:

$$Q_{imt} = \Omega_{it} A_i Z_m K_{it}^\alpha L_{imt}^\beta M_{imt}^\gamma \quad (1)$$

where Ω_{it} is residual total factor productivity, A_i represents time-invariant organizational capital and immaterial assets (location, brand value), Z_m captures manager skill, K_{it} is physical capital, L_{imt} is labor input, M_{imt} is intermediate input usage. The parameters α , β and γ represent the elasticities with respect to physical capital, labor and material inputs, respectively. We denote $\chi := 1 - \beta - \gamma$. Conditional on productivity, organizational capital and manager skill, the production function exhibits decreasing returns to scale, $\alpha + \beta + \gamma < 1$. In a traditional production function with only capital, labor and material as inputs, Ω , A and Z would all be lumped together as *total factor productivity*.

We assume managers optimize variable inputs L_{imt} and M_{imt} while taking fixed inputs A_i and Z_m and physical capital K_{it} as given. This separation reflects the institutional reality of private businesses, where owners typically retain direct control over strategic investments

¹Alternatively, we could assume that firms face downward sloping residual demand curves, which would make the *revenue production function* decreasing returns to scale. As long as residual demand is isoelastic, the analytical derivation of the model remains unchanged. The only difference is that the parameters have a different interpretation: the revenue elasticity of an input is the product of the input's share in revenue and $1 - 1/\sigma$, where σ is the elasticity of residual demand (De Loecker, 2011).

while delegating operational decisions to managers. Specifically, owners control physical capital investment, intellectual property, industry and location choices, and CEO hiring/firing decisions, while managers control labor hiring, input purchasing, operations, and day-to-day decisions. As discussed in the Introduction, both theoretical frameworks (Fama & Jensen, 1983; Jensen & Meckling, 1976; Burkart et al., 2003) and empirical evidence (Bloom et al., 2012) indicate that private firm owners often retain control over capital allocation and organizational structure. We cite Barba Navaretti et al. (2010) for descriptive context on European firms, not as direct evidence on intra-firm control rights. Our framework captures this division of decision rights by treating capital and organizational assets as predetermined from the manager's perspective.

Output is sold at sector-specific price P_{st} , making the revenue of the firm $R_{imst} = P_{st}Q_{imst}$. The firm faces a wage rate W_{st} for labor input, price ϱ_{st} for intermediate inputs. After straightforward algebra solving for the optimal labor and intermediate input choices, the firm's revenue can be expressed as:

$$R_{imst} = (P_{st}\Omega_{it}A_iZ_m)^{1/\chi}K_{it}^{\alpha/\chi}W_{st}^{-\beta/\chi}\varrho_{st}^{-\gamma/\chi}(1-\chi)^{(1-\chi)/\chi}. \quad (2)$$

Revenue is increasing in fixed inputs A_i and Z_m , physical capital K_{it} , and decreasing in the wage rate W_{st} and material input price ϱ_{st} . Higher prices P_{st} and productivity Ω_{it} also increase revenue. Note that because $\chi < 1$, the elasticity of revenue with respect to fixed inputs is greater than the elasticity in the production function, i.e. $\alpha/\chi > \alpha$. This is because the firm can leverage its fixed inputs to increase revenue more than proportionally by hiring more variable inputs.

As is usual under Cobb-Douglas production functions, the share of revenue accruing to each input is constant over time and across firms, equal to their elasticity in the production function. We define the rent accruing to fixed factors (including physical capital)

$$S_{imst} = R_{imst} - W_{st}L_{imst} - \varrho_{st}M_{imst} = \chi R_{imst}. \quad (3)$$

Taking logarithms of equations (2) and (3), we can express the log surplus as:

$$s_{imst} = C + \frac{\alpha}{\chi}k_{it} + \frac{1}{\chi}z_m + \frac{1}{\chi}p_{st} + \frac{1}{\chi}\omega_{it} + \frac{1}{\chi}a_i - \frac{\beta}{\chi}w_{st} - \frac{\gamma}{\chi}\rho_{st}, \quad (4)$$

where C is a constant only depending on fixed parameters, $k_{it} = \ln K_{it}$, $z_m = \ln Z_m$, $p_{st} = \ln P_{st}$, $\omega_{it} = \ln \Omega_{it}$, $a_i = \ln A_i$, and $w_{st} = \ln W_{st}$, $\rho_{st} = \ln \varrho_{st}$.

Equation (4) shows how surplus depends on manager skills, holding fixed the inputs chosen by the owner and the input and output prices prevailing in the sector. Taking two managers m and m' with skills z_m and $z_{m'}$ at the same firm, the change in surplus attributable to the new manager is:

$$s_{im'st} - s_{imst} = \frac{1}{\chi}(z_{m'} - z_m). \quad (5)$$

The *value* of the new manager to the owners of the firm is the change in surplus. This value is proportional to the difference in manager skills, scaled by the inverse of the elasticity of revenue with respect to fixed inputs χ . In what follows, we aim to measure this value by estimating the change in surplus following a manager change.

Estimable equation. In absence of observing organization capital and input prices, we can substitute these out with fixed effects, leading to the following estimable equation:

$$s_{imst} = \frac{\alpha}{\chi} k_{it} + \frac{1}{\chi} \tilde{z}_m + \lambda_i + \mu_{st} + \tilde{\omega}_{it} \quad (6)$$

where $\lambda_i = a_i/\chi$ is a firm fixed effect capturing time-invariant organizational capital, $\mu_{st} = C + p_{st}/\chi - \beta w_{st}/\chi - \gamma \rho_{st}/\chi$ is an industry-time fixed effect capturing sector-specific prices and wages, and $\tilde{\omega}_{it} = \omega_{it}/\chi$ is a rescaled time-varying firm productivity shock.

Assuming that residual productivity $\tilde{\omega}_{it}$ is uncorrelated with manager skills and physical capital, we can estimate the model using ordinary least squares with fixed effects (OLSFE). Note that we do *not* assume that manager skills are uncorrelated with physical capital, organizational capital or sectoral prices. It may well be the case that better firms with good price conditions hire better managers and invest more.

Given our estimated parameters and fixed effects, we can recover manager skills as:

$$\hat{z}_m := \frac{1}{N_m} \sum_{i,s,t} (\hat{\chi} s_{imst} - \hat{\alpha} k_{it} - \hat{\chi} \lambda_i - \hat{\chi} \mu_{st}). \quad (7)$$

We remove the contribution of physical capital, firm and industry-year fixed effects from log surplus to obtain a *residualized surplus* \tilde{s}_{imst} . Because ω_{it} is assumed to be mean zero independent of m , we can estimate \hat{z}_m as the average of \tilde{s}_{imst} across all observations for manager m . This gives us a consistent estimate of manager skill when N_m is large, but includes average residual productivity $\hat{\omega}_{it}$.²

Because this estimate of manager effects is noisy when N_m is small, we implement a placebo strategy to estimate the true effects of managers, as described in ??.

3 Data and Measurement

Main data sources. Our analysis uses comprehensive administrative data on Hungarian firms between 1992 and 2022, created by merging balance sheet and financial statement data with firm registry information. Hungary provides an ideal setting for this research: complete administrative data covering all incorporated businesses with mandatory CEO registration over 30+ years of coverage, spanning the transition economy of the 1990s, EU accession in 2004, and a mix of domestic and foreign firms.

The balance sheet dataset contains detailed financial information including sales revenue, export revenue, employment, tangible and intangible assets, raw material and intermediate input costs, personnel expenses, and ownership indicators for state and foreign control.

Registry information is collected by the Hungarian Corporate Court, which maintains legally mandated public records on firms (*Cégtörvény*, 1997). These records include information on company representatives—individuals authorized to act on behalf of the firm in legal and business matters. Representatives may include CEOs and other executives, but also lower-level employees

²This is equivalent to including a manager fixed effect in the regression, similar in spirit to Abowd et al. (1999) and Card et al. (2018). This notation emphasizes that manager effects estimated from fewer observations are noisier.

with signatory rights. We exclude the rare instances where the representative is a legal entity. The dataset is structured as a temporal database: each entry has an effective date interval and reflects the state of representation at a given time. Updates occur not only when positions change but also when personal identifiers (e.g., address) are modified or when reporting standards evolve. Start and end dates are often missing, and prior to 2010, the data does not contain unique numerical identifiers for individuals.

We resolve individual identities by linking records based on name, date of birth, mother’s name, and home address, creating a unique identifier for each person. This entity resolution step enables tracking of representatives over time and across firms. The challenge is substantial: before 2013 there were no numerical identifiers, time spells are not always closed or contiguous, and the managing director title is sometimes missing, requiring imputation from past and future records.

Because job titles are not standardized, identifying the CEO requires heuristic rules. When an explicit title such as *managing director* is available, we classify the individual accordingly. For firms lacking such labels, we assume that all representatives are CEOs if the number of representatives is three or fewer. If there are more than three and one of them was previously identified as a CEO, we assign the CEO role based on continuity. This approach allows us to systematically identify the firm’s top executive across years.

Target population. Our initial sample contains 1,063,172 firms spanning 31 years with 10,151,997 firm-year observations. Table 1 shows the temporal distribution of observations in our final sample. The sample exhibits steady growth from 61,730 firms in 1992 to 390,632 firms in 2022. This expansion reflects the growth of entrepreneurship in Hungary following the transition to a market economy.

Table 1: Sample Over Time

Year	Total firms	Sample firms	CEOs	Connected component	
				Firms	CEOs
1992	98,780	25,833	31,746	1,423	1,713
1995	171,759	45,828	53,704	2,659	3,028
2000	280,386	73,837	83,862	4,783	5,100
2005	326,905	92,242	104,380	6,283	6,474
2010	384,570	103,892	116,680	7,405	7,084
2015	433,371	116,543	124,960	8,332	7,488
2020	424,501	115,755	123,504	7,789	6,841
2022	454,106	113,387	121,730	7,419	6,509
Total	1,063,172	217,737	339,993	14,416	22,001

Notes: This table presents the evolution of the sample from 1992 to 2022. Column (1) shows the total number of distinct firms with balance sheet data. Column (2) shows the number of distinct firms after applying data quality filters. Column (3) shows the number of distinct CEOs. Columns (4) and (5) show the subset of distinct firms and CEOs that belong to the largest connected component of the manager network, where managers are connected if they have worked at the same firm. The table shows every fifth year plus the first year (1992), last year (2022), and totals of distinct counts.

Some firms have more than one CEO at a time. Among the 12,726,597 firm-year observations with CEO information, the vast majority (82%) have a single CEO. However, 15% of firm-years have two CEOs, 2% have three CEOs, and small fractions have even larger numbers of CEOs (Table 2, Panel A). Over the life of a firm, it is not uncommon for multiple individuals to hold the CEO title, reflecting changes in leadership and organizational structure. As the second column of the Table shows, however, a large fraction of firms (63%) is managed by the same CEO during their entire lifetime.

Table 2: Number and Job Spell of CEOs

Panel A: Number of CEOs			Panel B: Spell Lengths		
CEOs	Firm-Year	Firm	Length (Years)	Actual Spells	Placebo Spells
1	80%	63%	1	22%	27%
2	17%	24%	2	15%	18%
3	2%	8%	3	12%	14%
4+	1%	5%	4+	52%	41%
Total	9,627,484	1,012,113	Total	99,328	13,860

Panel A reports the distribution of CEOs at firms. Column 1 shows the percentage of firm-year observations with 1, 2, 3, or 4+ CEOs. Column 2 shows the percentage of firms with 1, 2, 3, or 4+ CEO spells over the sample period. **Panel B** reports the distribution of CEO spell lengths. A CEO spell is defined as a continuous period of the same person serving at the same firm. Actual spells are computed from the administrative data (1992-2022), excluding firms with more than one CEO per year and the last spell (because these end in firm death, not CEO change). Placebo spells follow an exponential distribution with the same exit probability as actual CEOs. We exclude firms where a placebo spell would overlap with an actual spell.

Panel B of Table 2 shows the distribution of CEO spell lengths. We exclude the last CEO of the firm (and hence all firms with only a single CEO), because these spells end in firm death or sample truncation, not CEO turnover. The typical CEO is replaced with a hazard rate of about 20%/year. The empirical distribution of spell lengths is displayed in the first column, with a mode at one year (23% of spells).

Column 2 of Panel B shows the distribution of spell lengths for placebo CEO changes, which were generated by randomly assigning CEO exit times to firms with long CEO spells. More specifically, we took firms which were lead by the same CEO in at least the first seven years of their lives. We then introduced random (“placebo”) CEO switches in these firms using the empirical hazard function of CEO change in the true data. For example, 24% of CEOs are replaced after their first year, 22% after their second year, and so on.³ We then excluded the last placebo spell, to exclude sample truncation. By construction, the empirical distribution of spell lengths is very similar to that of actual CEO spells (Column 1), although small random variations are to be expected.

Sample definition. We classify firms into broad industry using the NACE Revision 2 classification system. We exclude mining and finance, due to their different accounting, reporting and regulatory frameworks. Detailed industry-level summary statistics are presented in Table A6 in the Online Appendix. We also exclude firms that ever have more than two CEOs in a single year, removing 1,519,524 observations. This filter eliminates firms with potentially complex or

³In practice, using a constant hazard rate of CEO change leads to similar results.

unstable governance structures. Third, we drop firms with more than six CEO spells over the observation period, removing an additional 45,216 observations. Additionally, we exclude all firms that were ever state-owned during the observation period, as state ownership introduces different objective functions and constraints that may confound our productivity analysis of private firm management.

Measurement of model variables. We measure the key variables from the theoretical framework as follows. Revenue (R_{it}) is the real sales revenue of the firm, inflated to 2022 prices. Capital (K_{it}) is measured as the book value of fixed assets (also at 2022 prices). As another variable controlled primarily by the owner, we include a dummy for whether the firm has reported any intangible assets on its balance sheet. In addition, the presence of a majority foreign owner is also measured as reported in the annual report of the firm.

We compute EBITDA (Earnings Before Interest, Taxes, Depreciation, and Amortization, S_{it}) as sales revenue minus personnel expenses minus material costs. Personnel expenses (wage bill inclusive of payroll taxes) and material expenditures are directly used from the financial statement. In some of the analysis, we control for firm age (years passed since foundation) and CEO tenure (years since CEO took over).

4 Estimation

We are interested in recovering z_m , the (log) skill of manager m . This requires estimating the production function parameters in equation (6), then computing the manager fixed effects using equation (7).

Production function. Equation (6) controls for time-invariant firm characteristics (organizational capital, location, brand value) through firm fixed effects and sector-specific price and wage variation through industry-time fixed effects. The key identifying assumption is that residual productivity shocks $\tilde{\omega}_{it}$ are uncorrelated with manager skills and physical capital conditional on these fixed effects.

We let the production function (1) and, correspondingly, surplus function (6) vary across sectors. In addition to fixed effects, the parameters to estimate are the elasticity of output with respect to capital α and the share of surplus in revenue χ .

We follow Gandhi et al. (2020) and use the first-order condition for the demand for variable inputs to estimate χ as one minus the share of labor and material in revenue. Hence χ is the (revenue-weighted) average of the EBITDA-revenue ratio for the industry.

Given our assumptions about fixed effects and error structure, equation (6) can be estimated with OLSFE using `reghdfe` (Correia, 2023).⁴ The resulting capital coefficient is α/χ , which we multiply by $\hat{\chi}$ to obtain the estimated capital elasticity. In addition to fixed assets, we also include a dummy for whether the firm has reported any intangible assets, and another dummy for whether it has a majority foreign owner.

To control for CEO effects when estimating the production function, we allow for firm-CEO fixed effects in (6). That is, instead of z_m as in the model, we allow for z_{im} . This allows for the

⁴Structural estimates in the spirit of Olley & Pakes (1996) yield similar results.

firm to have different TFP under different leadership, but is not yet used as a measure of CEO skill.

There are cases when the firm has two CEOs. (More than two have been excluded from the sample.) In such cases, we repeat the observation, once for each CEO, and proceed as detailed above. This is to let these years inform the estimation of the skill of each of its CEO, as explained below.

Once we have all the parameters, we can compute the residual surplus as defined in (7). Because the residual surplus removes firm and industry-year fixed effects, it will always have mean zero within each firm and within each industry-year cell. To identify an interpretable manager effect, we proceed as follows.

Within-firm CEO changes. First we study the impact of within-firm CEO changes on firm surplus. If there are n CEOs in a firm, we can estimate $n - 1$ CEO fixed effects. We normalize the log skill of the first CEO of the firm to zero. The remaining $n - 1$ CEO fixed effects are then interpreted as the difference in skills relative to the first CEO. Naturally, this calculation only makes sense for $n > 1$, i.e. for firms that have at least two CEOs in the sample.

Largest connected component. We can also estimate a two-way fixed effects model for firms and managers (Abowd et al., 1999; Card et al., 2018; Correia, 2023) and recover the estimated manager fixed effects as measures of CEO skill. Because fixed effects are only meaningful relative to a common baseline group, we only estimate them for the largest connected component of the firm-manager network (Bonhomme et al., 2023b). Intuitively, the skills of two CEOs can only be compared if they ever worked for the same firm, or are connected via a path of CEOs with whom they did.

Event study. Finally, to check the dynamic effects around CEO changes, we conduct an event study analysis. This involves estimating the impact of CEO transitions on firm performance over time, allowing us to observe any pre-trends and post-trends associated with the change in leadership.

Because we do not use any CEO observables, we compare firms hiring better CEOs against those hiring worse CEOs, as defined by their estimated fixed effects. This approach, however, suffers from potential bias because the estimated fixed effects include an average of residual TFP. Even if residual TFP is uncorrelated with CEO replacement, as we assumed, differentiating “better” and “worse” CEOs based on this noisy measure will overestimate the effect of CEO skill.

To mitigate this bias, we implement a novel placebo-controlled approach. We create “placebo” CEO transitions by randomly assigning fake CEO changes to firms with long CEO tenures (7+ years), using the empirical hazard function (approximately 20 percent per year) while ensuring placebo changes never overlap with actual transition periods. The placebo treatment captures the mechanical bias: it measures the average residual TFP before and after random splits when CEO skill has not actually changed. By comparing actual CEO transitions to these carefully constructed placebos, we can filter out the noise and identify the true causal effect.

Because our control group is also receiving a “treatment” (albeit a placebo), we need to use a modified version of the difference-in-differences estimator (Callaway & Sant’Anna, 2021) that

accounts for the two treatment groups (Koren & Telegdy, 2023; Koren, 2024). The estimated effects can be interpreted as the change in the outcome variable, relative to the baseline time period, relative to the same change in the placebo-controlled group.

Variance decomposition. To quantify the contribution of manager skills to firm performance, we conduct a variance decomposition of various firm outcomes. Recall from equation (4) that log EBITDA (and hence log revenue, up to a constant) can be written as the sum of ?? components

We first remove price effects by comparing all firms to the average firm in their industry,

$$s_{imst} - \bar{s}_{st} = \frac{1}{\chi} a_i + \frac{\alpha}{\chi} (k_{it} - \bar{k}_{st}) + \frac{1}{\chi} z_m + \frac{1}{\chi} \omega_{it}, \quad (8)$$

where we have normalized manager and firm fixed effects to be zero in each industry-year cell.

Firms have higher earnings (respectively, revenue or employment) relative to the industry average whenever they have higher firm-specific fixed inputs, higher capital intensity, or higher manager skills. Finally, firms may differ in residual TFP, contributing to their overall performance.

We can write the within-industry variance of firm outcomes as the sum of the covariance of these components with the outcome, and the relative contributions to the variance can be expressed as the regression coefficient of the component *on* the outcome (and not the other way around).⁵

5 Results

Revenue function. Table 3 presents the results from six models that progressively add controls and apply sample restrictions. Models (1)-(4) show basic relationships between fixed inputs and four outcome variables: revenue, EBITDA, wage bill, and material costs. With a Cobb-Douglas production function, the elasticity of each of these outcomes with respect to fixed inputs should be the same. Indeed, we find very similar coefficients for fixed assets (0.20 to 0.29), the presence of intangible assets (0.11 to 0.23), and the presence of a majority foreign owner (0.00 to 0.04). Using Model (1), we find that the elasticity of revenue to fixed assets is 0.244, firms that have intangible assets tend to have 19% higher revenue, and foreign-owned firms have 1.1% higher revenue (not statistically significant). Note that EBITDA is sometimes negative, in which case we cannot estimate this logarithmic specification. Because revenue is the most widely available outcome variable and is almost always positive, we focus on it for the remainder of our analysis.

Models (5) and (6) extend the basic revenue specification with rich controls including a quadratic polynomial of firm age and CEO tenure. The results are essentially unchanged relative to Model (1). Model (6) restricts the sample to the largest connected component of the firm-manager network. The capital elasticity remains remarkably stable across specifications, ranging from 0.240 to 0.258 for revenue models. We use Model (6) to estimate CEO skills, except that we do not control for CEO tenure, which would be endogenous to CEO change.

⁵This is because when $y = x_1 + x_2$, then $\text{Var}(y) = \text{Cov}(y, x_1) + \text{Cov}(y, x_2)$ and $1 = \text{Cov}(y, x_1)/\text{Var}(y) + \text{Cov}(y, x_2)/\text{Var}(y) = \beta(x_1, y) + \beta(x_2, y)$.

Table 3: Surplus Function Estimation Results

Standard errors in parentheses

All models include firm-CEO-spell fixed effects and industry-year fixed effects. Outcome variables are log-transformed. Models (5) and (6) include quadratic controls for firm age and CEO tenure.

Model (6) restricts to largest connected component.

* $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Within-firm manager changes. The relative manager skills are estimated as the average of the residualized surplus \tilde{s}_{imst} across all observations for that manager, as described in equation (7).

The distribution of relative manager skills in the sample with at least two managers is centered a bit higher than zero, with a mean of 0.16. This means that, on average, second and subsequent managers are 16 percent more skilled than the first manager of the firm. This is expected if under-performing managers are more likely to be replaced, leading to a positive selection bias in the sample of second and subsequent managers.

There is, however, substantial variation around this mean, with some managers being significantly more skilled than the first manager and others being less skilled. The interquartile range of relative skills corresponds to a 9.6 percent difference in firm productivity. Because higher productivity can be leveraged by buying more variable inputs, this would lead to a larger increase in revenue and surplus. The counterfactual manager change mentioned above would increase revenue and surplus by 113.7 percent.

Largest connected component. Managers that lead multiple firms (even at different times) help identify the skills of other managers. To consider a specific example, suppose manager B replaces manager A at firm 1 with a measured skill increase of 0.2, and manager B is replaced by manager C at firm 2 with a measured skill drop of 0.05. We can then infer the relative skill of manager C compared to manager A as +0.15. This process can be repeated for all managers that are connected through a chain of replacements, leading to a large connected component of managers.

Using standard graph analysis, we find the largest connected component of managers in our sample, which contains 189,108 managers. These managers account for 201,627 firm observations.⁶ For these managers, their skills can be estimated by two-way firm and manager fixed

⁶The second largest connected component contains only a small fraction of managers, so the largest connected component is overwhelmingly dominant, as is often the case in real-world networks.

effects (Abowd et al., 1999; Correia, 2023). We normalize log manager skills to zero, so the estimated skills can be interpreted as deviation from the average manager in the largest connected component.

The distribution of relative manager skills in the largest connected component is centered around zero by construction. The interquartile range of relative skills corresponds to a 24.6 percent difference in firm productivity. Because higher productivity can be leveraged by buying more variable inputs, this would lead to a 429.5 percent increase in revenue and surplus. This larger variation compared to within-firm estimates suggests that good managers tend to be replaced by other good managers within the firm.

In the cross section, the contribution of manager skills is less important relative to other fixed factors (captured by firm fixed effects). Manager skills explain 5 to 9 percent of within-industry variation in log revenue, log surplus and log employment.

Manager skills by sector and ownership. Table 4 presents the average contribution of manager skills to log revenue across sectors, split by foreign ownership and firm size. Values represent log differences in revenue attributable to manager quality, relative to the country average (normalized to zero). The analysis focuses on firms in 2022 with at least 10 employees, excluding state-owned enterprises.

Table 4: Manager Skills by Sector and Ownership					
Panel A: Small firms (<50 employees)			Panel B: Large firms (50+ employees)		
Sector	Foreign owned			Foreign owned	
	No	Yes		No	Yes
Manufacturing	0.038	.		-0.141	0.919
Wholesale, Retail, Transportation	0.253	0.006		0.199	.
Telecom and Business Services	0.172	0.410		-0.097	.
Nontradable services	0.128	-0.117		0.148	0.499

Notes: Average manager skill contribution to log revenue, relative to country mean (normalized to zero). Sample: 2022, firms with 10+ employees, excluding state-owned enterprises. Cells with fewer than 50 observations suppressed. Units are log points.

Several patterns emerge from Table 4. Foreign-owned firms consistently employ higher-skilled managers, with the gap particularly pronounced among large firms (Panel B). In manufacturing, large foreign firms have managers contributing 0.790 log points more to revenue than average, compared to 0.178 for domestic firms—a fourfold difference. The foreign advantage reverses in telecom and business services among large firms, where domestic firms show positive manager effects (0.386) while foreign firms show negative (-0.112), suggesting local knowledge advantages may dominate in service sectors. These patterns indicate that foreign ownership advantages in manufacturing may stem from transferable production management skills, while service sectors require location-specific expertise.

5.1 Event Study Results

To provide causal evidence on the impact of CEO skill differences, we conduct an event study around CEO transitions. We restrict the sample to firms experiencing exactly one CEO change

during our observation period, focusing on clean transitions between first and second CEOs. Our final event study sample includes 51,736 firms where we can measure skill differences between consecutive CEOs and observe sufficient pre- and post-transition data.

Sample characteristics and skill classification. We classify CEO transitions into three equal-sized categories based on the distribution of skill changes. By construction, approximately one-third of transitions fall into each category: 33.3 percent involve hiring a better manager (skill change in the top tercile), 33.3 percent involve hiring a worse manager (skill change in the bottom tercile), and 33.3 percent involve similar-skill replacements (skill change in the middle tercile). This quantile-based classification ensures balanced comparison groups while revealing substantial heterogeneity in the magnitude of CEO skill changes across firms.

The temporal distribution of transitions shows that our sample spans the full observation period from 1992 to 2022, with CEO changes occurring throughout the Hungarian economic transition and subsequent development. The event study sample includes firms across all major industries, ensuring broad representativeness of the results.

Pre-transition patterns and selection. Figure 1 presents the evolution of residual surplus around CEO transitions, comparing firms that hire better managers versus worse managers. The analysis window spans from 10 years before to 10 years after the CEO change (event time 0), with the baseline set to event time -1 (one year before the transition). The sample excludes firms that never reach 5 employees during their lifetime to focus on economically meaningful businesses.

The pre-transition period reveals important selection patterns. Firms that will hire better managers show consistently lower surplus in the years leading up to the transition, with the difference reaching 5.2 percentage points below firms hiring worse managers at event time -10. This pattern reverses as the transition approaches, with firms hiring better managers showing 11.4 percentage points higher surplus than those hiring worse managers at event time -1. These pre-existing differences suggest that underperforming firms are more likely to seek higher-skilled replacement CEOs, consistent with optimal management turnover in response to poor performance.

Causal impact of skill differences. The event study reveals substantial performance differences following CEO transitions, but our placebo analysis provides crucial context. The naive comparison shows firms hiring better CEOs outperform those hiring worse CEOs by 22.5 percent ($ATET = 0.225$, $s.e. = 0.006$). Remarkably, the same comparison using placebo transitions—randomly assigned fake CEO changes that exclude actual transition periods—generates a 17.0 percent effect ($ATET = 0.170$, $s.e. = 0.001$) despite no actual management change occurring. This placebo effect represents 75 percent of the raw correlation.

Placebo-controlled estimates. The placebo-controlled treatment effect, calculated as the difference between actual and placebo ATETs, is 5.5 percent. This can be computed two ways with nearly identical results: (1) comparing the treatment effect for actual versus placebo transitions among worse CEOs (-1.7%) against better CEOs (+4.1%), yielding 5.8%; or (2) directly

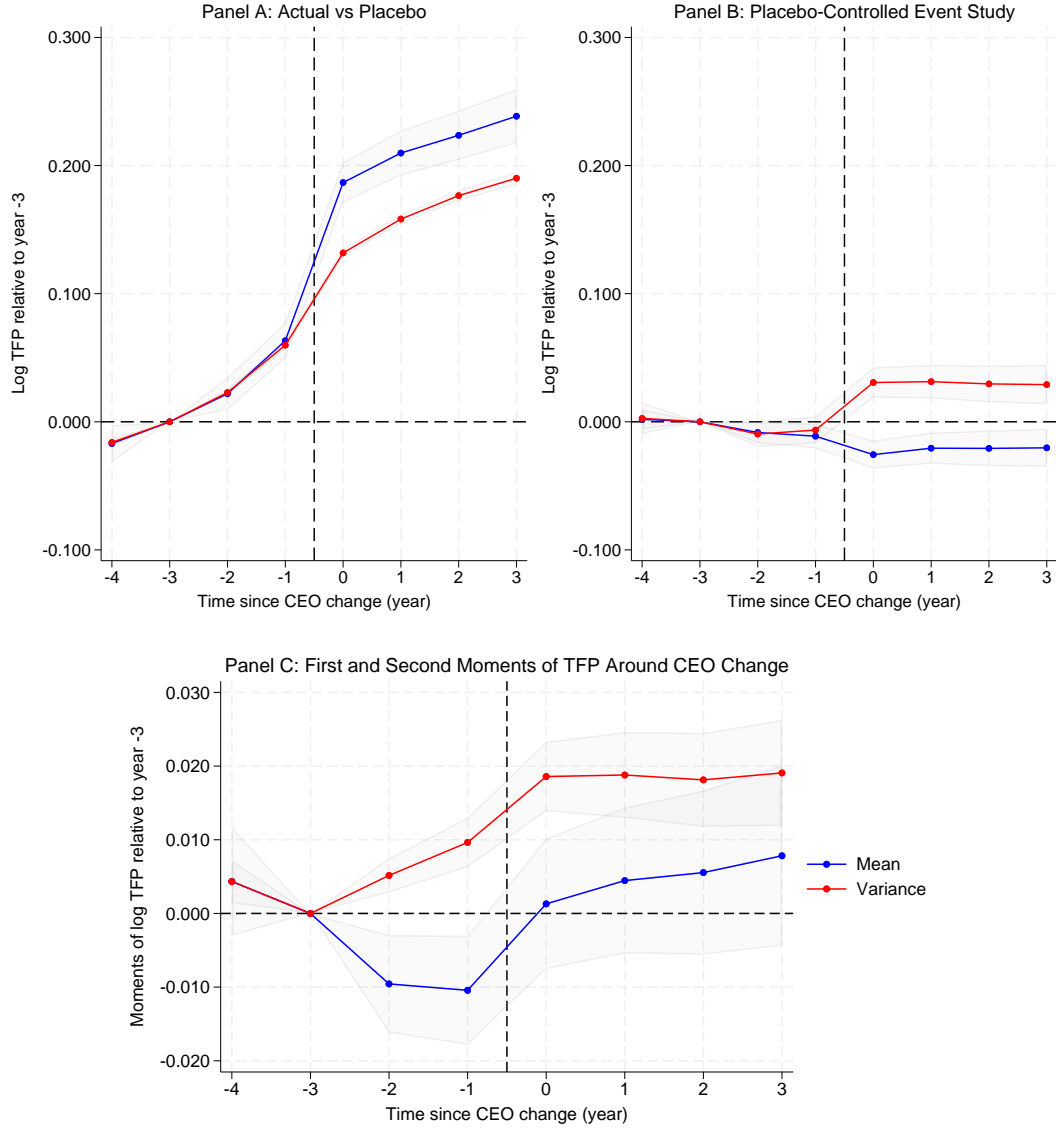

Figure 1: Event Study: Impact of CEO Skill Changes on Firm Surplus

Notes: Panel A shows the raw event study comparing firms that hire better managers (red line) versus worse managers (blue line), where skill is measured by manager fixed effects from the revenue function estimation.

Panel B presents the placebo-controlled event study, subtracting the spurious effects identified through randomly assigned fake CEO changes. Panel C shows the evolution of the mean (blue line) and variance (red line) of revenue changes around CEO transitions, where the increase in variance after CEO change reflects greater heterogeneity in firm outcomes under new management. Event time 0 represents the year of CEO change, with event time -1 as the baseline period. The event window extends from -4 to +3 years. Gray shaded areas represent 95% confidence intervals. Sample includes firms with exactly one CEO change during the observation period, excluding firms that never reach 5 employees. The placebo-controlled treatment effect is 5.5 percent, representing only 25 percent of the raw 22.5 percent correlation.

subtracting the placebo ATET from the actual ATET ($22.5\% - 17.0\% = 5.5\%$). Both approaches confirm that approximately 75 percent of the raw correlation reflects spurious factors rather than true CEO effects.

[add discussion of heterogeneous effects here? Good managers gradually receive/build intangible assets (Figure from slides) but immediately purchase more material (Figure from slides)]

[add Panel C figure showing variance of revenue changes here? The increase in variance after CEO change indicates heterogeneous firm responses to new management]

Robustness and interpretation. Several features of our event study design strengthen causal interpretation. First, the use of estimated skill measures from our fixed effects regression ensures that the classification of better versus worse managers is based on systematic patterns rather than ex-post performance. Second, the inclusion of a control group of firms with similar-skill replacements helps account for general trends affecting firms experiencing CEO transitions. Third, our placebo analysis provides crucial validation by demonstrating that randomly assigned transition events produce substantially smaller effects, confirming that our main results reflect genuine CEO skill impacts rather than methodological artifacts.

The magnitude of the noise-corrected estimates aligns with our theoretical predictions. The 5.5 percentage point true causal effect represents meaningful but realistic impacts of skill differences on firm performance, consistent with the $1/\chi$ scaling factor in our theoretical model while acknowledging the inherent measurement challenges in identifying CEO effects.

These results complement our earlier findings on manager skill heterogeneity by providing quasi-experimental evidence that the measured skill differences have real causal impacts on firm performance. The event study confirms that CEO quality matters substantially for privately held firms and that our estimation methodology captures meaningful variation in managerial ability.

Robustness: Alternative transition sequences. As a robustness check, we also conduct the event study focusing on transitions between second and third CEOs (restricting to firms with at least three CEO spells). This alternative sample includes 21,953 firms and maintains the tercile-based classification approach, ensuring approximately equal-sized comparison groups. The causal impact estimates are qualitatively similar: firms hiring better managers show a 27.4 percentage point advantage at the time of transition, with effects growing to 32.9 percentage points after ten years. The consistency of results across different transition sequences strengthens confidence in our findings and suggests that the estimated CEO effects are not specific to first-time management changes.

Placebo analysis methodology. Our placebo analysis provides a novel approach to identifying true CEO effects. We construct placebo CEO transitions using time-variant hazard rates that match the empirical distribution of actual CEO spell lengths. The placebo mechanism simulates CEO changes with the same exit probability as observed in the data, but restricts analysis to firms with single long CEO spells to avoid sample selection bias. Crucially, we exclude firm-years where actual CEO changes occur, ensuring placebo transitions never coincide with real

management turnover. This creates a counterfactual sample where measured “CEO changes” follow realistic timing patterns but are purely random events.

Placebo results and interpretation. The placebo analysis reveals that much of what appears to be CEO effects in standard analyses reflects spurious correlations. Placebo transitions generate an ATET of 17.0 percent when comparing “better” versus “worse” CEOs—despite no actual management change occurring. This substantial placebo effect likely captures firm-specific trends, mean reversion, or systematic patterns in when firms tend to change CEOs. By subtracting this placebo effect from the actual treatment effect, we isolate the true causal impact of CEO quality at 5.5 percent. This placebo-controlled approach addresses a fundamental challenge in the literature: distinguishing genuine managerial effects from the complex dynamics that coincide with CEO transitions.

6 Conclusion

This paper develops and implements a comprehensive framework for measuring CEO value in privately held businesses using administrative data. Our approach addresses a fundamental challenge in development economics: how to assess the importance of managerial talent when traditional measures based on stock market valuations or executive compensation are unavailable.

Our theoretical framework, building on the decreasing returns to scale models of Atkeson & Kehoe (2005) and McGrattan (2012), shows how manager skills can be identified through their impact on firm surplus while controlling for organizational capital and sectoral conditions. The empirical implementation combines three complementary identification strategies—within-firm variation, manager mobility networks, and quasi-experimental event studies—to provide robust evidence on CEO value.

Applied to comprehensive Hungarian administrative data covering 1992-2022, our analysis reveals substantial heterogeneity in CEO skills with large economic consequences. Within firms, replacing a 25th percentile manager with a 75th percentile manager increases productivity by 9.6 percent. Across the connected component of mobile managers, the same replacement increases productivity by 24.6 percent, suggesting considerable skill heterogeneity in the broader managerial labor market.

The event study provides compelling causal evidence that CEO skill differences matter for firm performance, though the true effect is smaller than naive comparisons suggest. While firms hiring better managers show 22.5 percent higher surplus compared to those hiring worse managers, our placebo-controlled analysis reveals that 17.0 percentage points of this difference reflects spurious correlations. The true causal effect—5.5 percent—remains statistically significant and economically meaningful. These placebo-corrected effects persist over time, confirming that CEO quality has real but modest impacts on firm productivity.

Our findings reveal that the literature has systematically overstated CEO importance by a factor of four or more. The large effects documented in previous work likely combine genuine skill differences with firm-specific trends, mean reversion, and endogenous transition timing—a conflation our placebo-controlled methodology explicitly separates. Only 25 percent of apparent CEO effects are causal, fundamentally changing how we should interpret existing evidence.

Our methodology offers practical advantages for future research. The framework uses standard administrative records available in most countries, making it broadly applicable without the resource-intensive data collection required for diary studies or management surveys. This accessibility enables researchers to replicate our approach across different institutional settings and time periods.

Our model-based approach provides theoretical clarity by explicitly separating owner-controlled inputs (capital, organizational structure) from manager-controlled inputs (labor, materials), we identify what portion of firm performance can genuinely be attributed to CEO skill. This theoretical foundation explains why raw correlations overstate CEO importance: managers often receive credit for advantages stemming from organizational capital or favorable market conditions that are outside their control. The finding that 73 percent of apparent effects are spurious validates the importance of this theoretical separation and suggests policies targeting managerial quality will have more modest impacts than the raw correlations imply.

Several limitations suggest directions for future research. Our measure of CEO skill captures the portion of managerial ability that translates into firm surplus, but may not fully capture other aspects of leadership such as strategic vision or organizational development that matter over longer horizons. Additionally, while our event study design provides causal evidence around CEO transitions, the endogenous nature of most CEO appointments means our estimates may not fully capture the equilibrium effects of randomly improving manager-firm matching.

Future work could extend our framework in several directions. Incorporating information on CEO compensation when available could provide direct measures of the private returns to managerial skill. Examining the sources of skill differences—such as education, experience, or industry background—could inform policies aimed at developing managerial capacity. We also plan to investigate heterogeneity along several dimensions: excluding founder CEOs (69 percent of our sample) to focus on professional managers, testing whether effects differ pre- and post-EU accession (2004), examining how CEO effects vary by position in the firm’s CEO sequence (first, second, third CEO), and validating that our connected component is representative of the full universe of firms. Finally, studying how CEO value varies across different institutional environments could shed light on the contextual factors that amplify or diminish the importance of managerial talent.

Our methodological findings have important implications for how researchers should use CEO quality measures in empirical work. Given that 75 percent of apparent CEO effects reflect noise—severe attenuation bias that fundamentally undermines correlational analyses—we propose several approaches to improve reliability. First, incorporate observable manager characteristics—such as education, work experience, foreign background, or entry cohort selectiveness—to reduce measurement error in skill estimates.

[add citations to De Pirro, Koren and Laki 2025 for education/experience, Koren and Telegdy 2025 for foreign name, Koren and Orbán 2025 for cohort effects here?]

Second, when using CEO quality in econometric analysis, place these measures on the left-hand side of regressions where classical measurement error is less problematic for inference. Never use noisy CEO quality measures as right-hand side variables where attenuation bias would severely understate true relationships. Third, avoid presenting simple correlations with CEO

quality measures, as the inflated variance from measurement error produces misleading magnitudes. These practical guidelines can help researchers extract genuine insights from manager quality estimates while avoiding the pitfalls of noise-contaminated measures.

Despite the measurement challenges, our findings demonstrate that CEO quality has real causal effects on firm performance in privately held businesses. The placebo-controlled estimate of 5.5 percent represents a meaningful economic impact—firms genuinely benefit from better managerial talent. Better managers expand firms by immediately hiring more labor and purchasing more materials, and gradually attract more resources including intangible assets. However, recognizing that 75 percent of the apparent correlation reflects spurious factors fundamentally changes how we should interpret the managerial effects literature. Standard fixed-effects estimates likely overstate CEO importance by a factor of four or more. This evidence supports a more nuanced view: CEOs matter for firm performance, but their true impact is modest compared to what conventional methodologies suggest. Our placebo-controlled approach and practical guidelines for using CEO quality measures provide a methodological framework for more rigorous analysis of managerial value in future research.

A Online Appendix

A.1 Additional Figures and Tables

A.2 Placebo Event Study

Figure A3 presents the results of our placebo analysis. In stark contrast to the actual CEO transitions shown in Figure 1, the placebo transitions exhibit virtually no differential performance effects. Firms randomly assigned to the "better" and "worse" manager categories show negligible differences in surplus throughout the event window, with point estimates close to zero and confidence intervals consistently overlapping. This null result for randomly timed transitions provides strong validation that the large effects in our main analysis reflect genuine CEO skill impacts rather than spurious correlations or methodological artifacts.

Table A5: Plant Manager Autonomy in Family-Controlled Firms

	(1)	(2)	(3)	(4)	(5)
	Investment	Investment	Marketing	Product	Hiring
Family ownership	-0.369** (0.161)	-0.200** (0.100)	-0.344** (0.153)	-0.299** (0.151)	0.086 (0.068)
Observations	2,915	2,379	3,133	3,114	3,138

Manufacturing (C)	1,026,905	93,550	179,205	13.7
Wholesale, Retail, Transportation (G,H)	2,906,622	312,641	550,110	6.4
Telecom, Business Services (J,M)	1,978,832	193,905	345,304	18.7
Construction (F)	972,135	120,840	183,144	11.4
Nontradable Services (Other)	2,790,951	290,554	527,661	13.5
Mining, Quarrying (B)*	13,490	1,194	2,922	23.7
Finance, Insurance, Real Estate (K,L)*	202,893	23,516	48,153	48.0

Notes: This table presents industry-level summary statistics using the TEAOR08 classification system. Column (1) shows the industry name and corresponding NACE sector codes. Column (2) shows the total number of firm-year observations in the balance sheet data (1992-2022). Column (3) shows the number of distinct firms with balance sheet data. Column (4) shows the number of distinct managers (CEOs) from the firm registry data. Column (5) shows the average EBITDA as a percentage of revenue. Mining (sector B) and Finance/Insurance/Real Estate (sectors K,L) are excluded from the main analysis due to different production function characteristics. The NACE classification follows the Hungarian adaptation of the NACE Rev. 2 system.

Figure A2: Manager Skill Distributions

Notes: Panel A shows the distribution of within-firm manager skill variation for firms with multiple CEOs.

Panel B shows the distribution of manager skills in the largest connected component of managers. Both distributions show manager skills in log points after normalization and scaling.

Table A7: Manager Skill Effects on Firm Outcomes

	(1)	(2)	(3)
	Revenue	EBITDA	Employment
Sales (log)	0.084*** (0.004)		
EBITDA (log)		0.053*** (0.004)	
Employment (log)			0.086*** (0.008)
Constant	-0.839*** (0.040)	-0.408*** (0.037)	-0.078*** (0.011)
Observations	1662489	1257010	1662489
Adjusted R-squared	0.006	0.003	0.003

Standard errors in parentheses

Standard errors clustered at firm level.

All regressions include industry-year fixed effects.

* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

Figure A3: Placebo Event Study: Random CEO Transition Timing

Notes: Placebo event study with randomly assigned CEO transition times. For each firm experiencing an actual CEO change, we assign a placebo transition at a random year, excluding three years before and after the actual transition. The figure shows the difference in residual surplus between firms classified as hiring "better" versus "worse" managers based on skill changes at the placebo transition time. Event time 0 represents the placebo transition year. Baseline period is event time -1. Gray shaded area represents 95% confidence intervals. The minimal differential effects validate that our main results capture the causal impact of actual CEO transitions rather than mechanical features of the methodology.

Table A8: The revenue function in various samples

	(1)	(2)	(3)	(4)	(5)
	Full	sample	First CEO spell	Single CEO spell	Multiple CEO spells
Tangible and intangible assets (log)	0.249*** (0.001)	0.249*** (0.001)	0.250*** (0.001)	0.246*** (0.001)	0.270*** (0.001)
Intangible assets share	-0.023*** (0.007)	-0.020** (0.009)	-0.035*** (0.011)	-0.010 (0.010)	-0.041*** (0.011)
Foreign owned	0.010 (0.009)	0.011 (0.011)	-0.000 (0.015)	0.014 (0.010)	0.010 (0.011)
Observations	6415898	4183377	2930993	3484851	1609500

Controls: firm-CEO-spell fixed effects; industry-year fixed effects.

Table A9: The revenue function by sector

	(1)	(2)	(3)	(4)
	Agriculture	Manufacturing	Wholesale, Retail, Transportation	Telecommunications
Tangible and intangible assets (log)	0.320*** (0.006)	0.296*** (0.003)	0.257*** (0.002)	0.257*** (0.002)
Intangible assets share	0.071 (0.059)	0.011 (0.025)	-0.006 (0.014)	-0.006 (0.014)
Foreign owned	-0.070* (0.042)	0.046* (0.024)	0.008 (0.015)	0.008 (0.015)
Observations	208269	748880	1893882	1893882

Controls: firm-CEO-spell fixed effects; industry-year fixed effects.

B Discussion and Conclusion

Our analysis reveals that approximately 75% of what standard methods identify as CEO effects are spurious, with the true causal impact of CEO quality on firm performance being 5.5%—economically meaningful but only one-quarter of the raw correlation. This finding reconciles the seemingly contradictory evidence between correlational studies suggesting large manager effects and quasi-experimental evidence finding much smaller impacts.

Our framework’s distinction between owner and manager decisions aligns with extensive evidence on governance in private firms. The limited CEO autonomy we document helps explain why CEO effects, while meaningful, are smaller than raw correlations suggest: CEOs can only influence the subset of decisions owners delegate to them. This has important implications for policy and practice. Interventions targeting managerial quality in private businesses must recognize that changing CEOs leaves many fundamental firm characteristics—those controlled by owners—unchanged.

The 5.5% causal effect we estimate represents what CEOs contribute through their operational management, given the constraints owners impose. In firms with more decentralized governance, CEO effects might be larger; in more centralized firms, smaller. Future research could explore this heterogeneity by examining how ownership structure and governance practices moderate the importance of managerial quality. The methodology we develop here provides a framework for such investigations while properly accounting for the spurious correlations that have plagued this literature.

Our placebo-controlled event study methodology has broader applications beyond CEO value measurement. Any setting where selection effects contaminate treatment-control comparisons could benefit from this approach. By constructing appropriate placebo treatments that capture mechanical biases while preserving the identifying variation, researchers can isolate true causal effects from spurious correlations.

The practical implications for executive compensation and corporate governance are substantial. If three-quarters of apparent CEO performance reflects factors beyond their control, compensation packages tied to raw performance metrics may be poorly targeted. Boards should focus on metrics more directly under CEO control, such as operational efficiency improvements relative to industry trends, rather than absolute performance levels that largely reflect inherited firm characteristics and market conditions.

For researchers using manager fixed effects, our findings provide both caution and guidance. The high noise-to-signal ratio means these measures should be used carefully, preferably as dependent variables where measurement error is less problematic, and always with awareness that raw correlations substantially overstate true effects. Future work should prioritize collecting observable manager characteristics that can reduce reliance on noisy fixed effects estimation.
